Secure Data Sharing in Cloud Computing Using Revocable-Storage Identity-Based Encryption

Jianghong Wei, Wenfen Liu, Xuexian Hu

Abstract—Cloud computing provides a flexible and convenient way for data sharing, which brings various benefits for both the society and individuals. But there exists a natural resistance for users to directly outsource the shared data to the cloud server since the data often contain valuable information. Thus, it is necessary to place cryptographically enhanced access control on the shared data. Identity-based encryption is a promising cryptographical primitive to build a practical data sharing system. However, access control is not static. That is, when some user’s authorization is expired, there should be a mechanism that can remove him/her from the system. Consequently, the revoked user cannot access both the previously and subsequently shared data. To this end, we propose a notion called revocable-storage identity-based encryption (RS-IBE), which can provide the forward/backward security of ciphertext by introducing the functionalities of user revocation and ciphertext update simultaneously. Furthermore, we present a concrete construction of RS-IBE, and prove its security in the defined security model. The performance comparisons indicate that the proposed RS-IBE scheme has advantages in terms of functionality and efficiency, and thus is feasible for a practical and cost-effective data-sharing system. Finally, we provide implementation results of the proposed scheme to demonstrate its practicability.

Index Terms—Cloud computing, data sharing, revocation, Identity-based encryption, ciphertext update, decryption key exposure.

1 INTRODUCTION

Cloud computing is a paradigm that provides massive computation capacity and huge memory space at a low cost [1]. It enables users to get intended services irrespective of time and location across multiple platforms (e.g., mobile devices, personal computers), and thus brings great convenience to cloud users. Among numerous services provided by cloud computing, cloud storage service, such as Apple’s iCloud [2], Microsoft’s Azure [3] and Amazon’s S3 [4], can offer a more flexible and easy way to share data over the Internet, which provides various benefits for our society [5], [6]. However, it also suffers from several security threats, which are the primary concerns of cloud users [7].

Firstly, outsourcing data to cloud server implies that data is out of control of users. This may cause users’ hesitation since the outsourced data usually contain valuable and sensitive information. Secondly, data sharing is often implemented in an open and hostile environment, and cloud server would become a target of attacks. Even worse, cloud server itself may reveal users’ data for illegal profit. Thirdly, data sharing is not static. That is, when a user’s authorization gets expired, he/she should no longer possess the privilege of accessing the previously and subsequently shared data. Therefore, while outsourcing data to cloud server, users also want to control access to these data such that only those currently authorized users can share the outsourced data.

A natural solution to conquer the aforementioned problem is to use cryptographically enforced access control such as identity-based encryption (IBE). Furthermore, to overcome the above security threats, such kind of identity-based access control placed on the shared data should meet the following security goals:

- **Data confidentiality**: Unauthorized users should be prevented from accessing the plaintext of the shared data stored in the cloud server. In addition, the cloud server, which is supposed to be honest but curious, should also be deterred from knowing plaintext of the shared data.
- **Backward secrecy**: Backward secrecy means that, when a user’s authorization is expired, or a user’s secret key is compromised, he/she should be prevented from accessing the plaintext of the subsequently shared data that are still encrypted under his/her identity.
- **Forward secrecy**: Forward secrecy means that, when a user’s authority is expired, or a user’s secret key is compromised, he/she should be prevented from accessing the plaintext of the shared data that can be previously accessed by him/her.

The specific problem addressed in this paper is how to construct a fundamental identity-based cryptographical tool to achieve the above security goals. We also note that there exist other security issues that are equally important for a practical system of data sharing, such as the authenticity and availability of the shared data [8], [9], [10], [11], [12]. But the research on these issues is beyond the scope of this paper.

1.1 Motivation

It seems that the concept of revocable identity-based encryption (RIBE) might be a promising approach that fulfills...
the aforementioned security requirements for data sharing. RIBE features a mechanism that enables a sender to append the current time period to the ciphertext such that the receiver can decrypt the ciphertext only under the condition that he/she is not revoked at that time period. As indicated in Figure 1, a RIBE-based data sharing system works as follows:

Step 1: The data provider (e.g., David) first decides the users (e.g., Alice and Bob) who can share the data. Then, David encrypts the data under the identities Alice and Bob, and uploads the ciphertext of the shared data to the cloud server.

Step 2: When either Alice or Bob wants to get the shared data, she or he can download and decrypt the corresponding ciphertext. However, for an unauthorized user and the cloud server, the plaintext of the shared data is not available.

Step 3: In some cases, e.g., Alice’s authorization gets expired, David can download the ciphertext of the shared data, and then decrypt-then-re-encrypt the shared data such that Alice is prevented from accessing the plaintext of the shared data, and then upload the re-encrypted data to the cloud server again.

Obviously, such a data sharing system can provide confidentiality and backward secrecy. Furthermore, the method of decrypting and re-encrypting all the shared data can ensure forward secrecy. However, this brings new challenges. Note that the process of decrypt-then-re-encrypt necessarily involves users’ secret key information, which makes the overall data sharing system vulnerable to new attacks. In general, the use of secret key should be limited to only usual decryption, and it is inadvisable to update the ciphertext periodically by using secret key.

Another challenge comes from efficiency. To update the ciphertext of the shared data, the data provider has to frequently carry out the procedure of download-decrypt-re-encrypt-upload. This process brings great communication and computation cost, and thus is cumbersome and undesirable for cloud users with low capacity of computation and storage. One method to avoid this problem is to require the cloud server to directly re-encrypt the ciphertext of the shared data. However, this may introduce ciphertext extension, namely, the size of the ciphertext of the shared data is linear in the number of times the shared data have been updated. In addition, the technique of proxy re-encryption can also be used to conquer the aforementioned problem of efficiency. Unfortunately, it also requires users to interact with the cloud server in order to update the ciphertext of the shared data.

1.2 Related work

1.2.1 Revocable identity-based encryption

The concept of identity-based encryption was introduced by Shamir [13], and conveniently instantiated by Boneh and Franklin [14]. IBE eliminates the need for providing a public key infrastructure (PKI). Regardless of the setting of IBE or PKI, there must be an approach to revoke users from the system when necessary, e.g., the authority of some user is expired or the secret key of some user is disclosed. In the traditional PKI setting, the problem of revocation has been well studied [15], [16], [17], [18], [19], and several techniques are widely approved, such as certificate revocation list or appending validity periods to certificates. However, there are only a few studies on revocation in the setting of IBE.

Boneh and Franklin [14] first proposed a natural revocation way for IBE. They appended the current time period to the ciphertext, and non-revoked users periodically received private keys for each time period from the key authority. Unfortunately, such a solution is not scalable, since it requires the key authority to perform linear work in the number of non-revoked users. In addition, a secure channel is essential for the key authority and non-revoked users to transmit new keys. To conquer this problem, Boldyreva, Goyal and Kumar [20] introduced a novel approach to achieve efficient revocation. They used a binary tree to manage identity such that their RIBE scheme reduces the complexity of key revocation to logarithmic (instead of linear) in the maximum number of system users. However, this scheme only achieves selective security. Subsequently, by using the aforementioned revocation technique, Libert and Vergnaud [21] proposed an adaptively secure RIBE scheme based on a variant of Water’s IBE scheme [22], Chen et al. [23] constructed a RIBE scheme from lattices.

Recently, Seo and Emura [24] proposed an efficient RIBE scheme resistant to a realistic threat called decryption key exposure, which means that the disclosure of decryption key for current time period has no effect on the security of decryption keys for other time periods. Inspired by the above work and [25], Liang et al. [26] introduced a cloud-based revocable identity-based proxy re-encryption that supports user revocation and ciphertext update. To reduce the complexity of revocation, they utilized a broadcast encryption scheme [27] to encrypt the ciphertext of the update key, which is independent of users, such that only non-revoked users can decrypt the update key. However, this kind of revocation method cannot resist the collusion of revoked users and malicious non-revoked users as malicious non-revoked users can share the update key with those revoked users. Furthermore, to update the ciphertext, the key authority in their scheme needs to maintain a table for each user to...
produce the re-encryption key for each time period, which significantly increases the key authority's workload.

1.2.2 Forward-secure cryptosystems

In 1997, Anderson [28] introduced the notion of forward security in the setting of signature to limit the damage of key exposure. The core idea is dividing the whole lifetime of a private key into $T$ discrete time periods, such that the compromise of the private key for current time period cannot enable an adversary to produce valid signatures for previous time periods. Subsequently, Bellare and Miner provided formal definitions of forward-secure signature and presented practical solutions. Since then, a large number of forward-secure signature schemes [29], [30], [31], [32], [33] has been proposed.

In the context of encryption, Canetti, Halevi and Katz [34] proposed the first forward-secure public-key encryption scheme. Specifically, they firstly constructed a binary tree encryption, and then transformed it into a forward-secure encryption with provable security in the random oracle model. Based on Canetti et al's approach, Yao et al. [35] proposed a forward-secure hierarchical IBE by employing two hierarchical IBE schemes, and Nieto et al. [36] designed a forward-secure hierarchical predicate encryption.

Particularly, by combining Boldyreva et al.'s [20] re-encryption technique and the aforementioned idea of forward security1, in CRYPTO 2012 Sahai, Seyalioglu and Waters [37] proposed a generic construction of so-called revocable-storage attribute-based encryption, which supports user revocation and ciphertext update simultaneously. In other words, their construction provides both forward and backward secrecy. What must be pointed out is that the process of ciphertext update of this construction only needs public information. However, their construction cannot be resistant to decryption key exposure, since the decryption is a matching result of private key and update key.

1.3 Our contributions

In this paper, we introduce a notion called revocable-storage identity-based encryption (RS-IBE) for building a cost-effective data sharing system that fulfills the three security goals. More precisely, the following achievements are captured in this paper:

- We provide formal definitions for RS-IBE and its corresponding security model;
- We present a concrete construction of RS-IBE. The proposed scheme can provide confidentiality and backward/forward secrecy simultaneously;
- We prove the security of the proposed scheme in the standard model, under the decisional $\ell$-Bilinear Diffie-Hellman Exponent ($\ell$-BDHE) assumption. In addition, the proposed scheme can withstand decryption key exposure;
- The proposed scheme is efficient in the following ways:
  - The procedure of ciphertext update only needs public information. Note that no previous identity-based encryption schemes in the literature can provide this feature;
  - The additional computation and storage complexity, which are brought in by the forward secrecy, is all upper bounded by $O(\log(T)^2)$, where $T$ is the total number of time periods.

Outline. The remainder of this paper is structured as follows: In section 2, we introduce the preliminaries involved in our construction. Then we present the definitions of RS-IBE in section 3, and provide the concrete construction in section 4, followed with the corresponding security analysis, performance discussions, and the implementation results of the scheme. Finally, we conclude in section 5.

2 Preliminaries

In this section, we first briefly present the basic concepts on bilinear pairing and decisional $\ell$-BDHE assumption. Then, an algorithm used to perform efficient revocation is introduced.

2.1 Bilinear pairing and complexity assumption

Definition 1 (Bilinear pairing). Let $G_1$ and $G_2$ be two cyclic groups with prime order $q$, and $g$ be a generator of $G_1$. A bilinear pairing is a map $e : G_1 \times G_1 \rightarrow G_2$ with the following properties:

1. Bilinearity: $e(u^a, h^b) = e(u, h)^{ab}$ for all $u, h \in G_1$, $a, b \in \mathbb{Z}_q$.
2. Non-degeneracy: $e(g, g) \neq 1$.
3. Computability: There exists an efficient algorithm to compute $e(u, h)$ for any $u, h \in G_1$.

Definition 2 (Decisional $\ell$-BDHE Assumption). The decisional $\ell$-BDHE problem is formalized as follows. Choose a group $G_1$ with prime order $p$ according to the security parameter $\lambda$. Select a generator $g$ of $G_1$ and $a, s \leftarrow \mathbb{Z}_p$, and let $f_1 = g^a$. Provide the vector $f = (g, g^a, f_1, \ldots, f_\ell, f_{\ell+2}, \ldots, f_{2\ell})$ and an element $D \in G_2$ to a probabilistic polynomial-time (PPT) algorithm $\mathcal{C}$, it outputs 0 to indicate that $D = e(g^s, g^{a+1})$, and outputs 1 to indicate that $D$ is a random element from $G_2$.

The advantage of $\mathcal{C}$ solving the decisional $\ell$-BDHE problem in $G_1$ is defined as follows:

$$\text{Adv}_{\mathcal{C}}^{\ell-\text{BDHE}}(\lambda) = \left| \Pr[\mathcal{C}(f, D = e(g^s, g^{a+1})) = 0] - \Pr[\mathcal{C}(f, D \leftarrow \mathbb{R} G_2) = 0] \right|. $$

We say that the decisional $\ell$-BDHE assumption holds in $G_1$ provided that no PPT algorithm can solve the decisional $\ell$-BDHE problem with a non-negligible advantage.

2.2 KUNodes algorithm

Our RS-IBE scheme uses the same binary tree structure introduced by Boldyreva, Goyal and Kumar [20] to achieve efficient revocation. To describe the revocation mechanism, we first present several notations. Denote by $\varepsilon$ the root node of the binary tree $BT$, and $\text{Path}(\eta)$ the set of nodes on the path from $\varepsilon$ to the leaf node $\eta$ (including $\varepsilon$ and $\eta$). For a non-leaf node $\theta$, we let $\theta_l$ and $\theta_r$ stand for its left and right
child, respectively. Given a time period $t$ and revocations list $RL$, which is comprised of the tuples $(\eta_i, t_i)$ indicating that the node $\eta_i$ was revoked at time period $t_i$, the algorithm KUNodes$(BT, RL, t)$ outputs the smallest subset $Y$ of nodes of $BT$ such that $Y$ contains an ancestor for each node that is not revoked before the time period $t$.

Fig. 2. An instance of the algorithm KUNodes

Informally, to identify the set $Y$, the algorithm first marks all the ancestors of revoked nodes as revoked, then outputs all the non-revoked children of revoked nodes. As an example, we present two instances of the algorithm KUNodes in Figure 2. The formal description is given below.

Algorithm 1 KUNodes$(BT, RL, t)$

1. $X, Y \leftarrow \emptyset$
2. for all $(\eta_i, t_i) \in RL$ do
3.  if $t_i \leq t$ then
4.    AddPath($\eta_i$) to X
5.  end if
6.  end for
7.  for all $\theta \in X$ do
8.    if $\theta_i \notin X$ then
9.      Add $\theta_i$ to Y
10.    end if
11.  end for
12. for all $\eta \in X$ do
13.    if $\eta_i \notin X$ then
14.      Add $\eta_i$ to Y
15.    end if
16.  end for
17.  if $Y = \emptyset$ then
18.    Add the root node $\varepsilon$ to Y
19.  end if
20. return $Y$

3 Definition and security model of RS-IBE

In this section, we first provide the formal definition of RS-IBE, and then give the corresponding security model.

3.1 Syntax of RS-IBE

Definition 3 (Revocable-Storage Identity-Based Encryption). A revocable-storage identity-based encryption scheme with message space $M$, identity space $I$ and total number of time periods $T$ is comprised of the following seven polynomial time algorithms:

- **Setup**$(1^\lambda, T, N)$: The setup algorithm takes as input the security parameter $\lambda$, the time bound $T$ and the maximum number of system users $N$, and it outputs the public parameter $PP$ and the master secret key $MSK$, associated with the initial revocation list $RL = \emptyset$ and state $st$.
- **PKGen**$(PP, MSK, ID)$: The private key generation algorithm takes as input $PP$, $MSK$ and an identity $ID \in I$, and it generates a private key $SK_{ID}$ for $ID$ and an updated state $st$.
- **KeyUpdate**$(PP, MSK, RL, t, st)$: The key update algorithm takes as input $PP$, $MSK$, the current revocation list $RL$, the key update time $t \leq T$ and the state $st$, it outputs the key update $KU_t$.
- **DKGen**$(PP, SK_{ID}, KU_t)$: The decryption key generation algorithm takes as input $PP$, $SK_{ID}$ and $KU_t$, and it generates a decryption key $DK_{ID, t}$ for $ID$ with time period $t$ or a symbol $\bot$ to illustrate that $ID$ has been previously revoked.
- **Encrypt**$(PP, ID, t, M)$: The encryption algorithm takes as input $PP$, an identity $ID$, a time period $t \leq T$, and a message $M \in M$ to be encrypted, and outputs a ciphertext $CT_{ID,t}$.
- **CTUpdate**$(PP, CT_{ID,t}, t')$: The ciphertext update algorithm takes as input $PP$, $CT_{ID,t}$ and a new time period $t' \geq t$, and it outputs an updated ciphertext $CT_{ID,t'}$.
- **Decrypt**$(PP, CT_{ID,t}, DK_{ID,t'})$: The decryption algorithm takes as input $PP$, $CT_{ID,t}$, $DK_{ID,t}$, and it recovers the encrypted message $M$ or a distinguished symbol $\bot$ indicating that $CT_{ID,t}$ is an invalid ciphertext.
- **Revoke**$(PP, ID, RL, t, st)$: The revocation algorithm takes as input $PP$, an identity $ID \in I$ to be revoked, the current revocation list $RL$, a state $st$ and revocation time period $t \leq T$, and it updates $RL$ to a new one.

Definition 4 (Correctness of RS-IBE). We say that a RS-IBE scheme is correct provided that, for any $(PP, MSK, RL, st) \leftarrow$ Setup$(1^\lambda, T, N), ID \in I, t \leq T, M \in M$, all possible states $st$ and a revocation lists $RL$, if $ID$ is not revoked at time period $t$, then for $(SK_{ID}, sk) \leftarrow$ PKGen$(PP, MSK, ID)$, $KU_t \leftarrow$ KeyUpdate$(PP, MSK, RL, t, sk)$, $DK_{ID,t} \leftarrow$ DKGen$(PP, SK_{ID}, KU_t)$, and $CT_{ID,t} \leftarrow$ Encrypt$(PP, ID, t, M)$, it is required that:

- If $t \geq t'$, then $\text{Decrypt}(PP, CT_{ID,t'}, DK_{ID,t}) = M$. Otherwise, $\text{Decrypt}(PP, CT_{ID,t'}, DK_{ID,t}) = \bot$ with all but negligible probability.
- For $t \geq t'$, it holds that $\text{CTUpdate}(PP, CT_{ID,t'}, t) \equiv \text{Encrypt}(PP, ID, t, M)$ holds.

Here, $\equiv$ indicates equality in statistical distribution.

3.2 Security model

Definition 5 (IND-RID-CPA). A RS-IBE scheme is IND-RID-CPA secure provided that for any PPT adversary $A$, it has negligible advantage in the following security game between a challenger $C$ and the adversary $A$:

- Setup, $C$ performs Setup$(1^\lambda, T, N) \rightarrow (PP, MSK)$ and sends $PP$ to $A$;
• Phase 1. A makes the following queries in an adaptive way:
  a. \(O_{SK}(ID)\): C performs \(\text{PKGen}(PP, MSK, ID)\) \(\rightarrow\) \((SK_{ID}, \theta)\) and returns \(SK_{ID}\) to \(A\);
  b. \(O_{KU}(t)\): C runs \(\text{KeyUpdate}(PP, MSK, RL, t, st)\) \(\rightarrow\) \(KU_t\) and returns \(KU_t\);
  c. \(O_{DK}(ID, t)\): C runs \(\text{PKGen}(PP, MSK, ID)\) \(\rightarrow\) \((SK_{ID}, \theta)\) and \(\text{DKGen}(PP, SK_{ID}, KU_t)\) \(\rightarrow\) \(DK_{ID,t}\) and forwards \(DK_{ID,t}\) to \(A\);
  d. \(O_{CT}(ID, t)\): C updates the current revocation list \(RL\) by running \(\text{Revolve}(PP, ID, RL, t, st)\) \(\rightarrow\) \(RL\) and returns the updated RL to \(A\);

• Challenge. A signals the query is over and sends \((M_0, M_1, ID^*, t^*, st)\) to \(C\) subject to the restriction that \(M_0, M_1 \in \mathcal{M}\) and \(|M_0| = |M_1|\). Then, \(C\) chooses a random bit \(\beta \in \{0, 1\}\), and returns the challenged ciphertext \(CT_{ID, t^*} \leftarrow \text{Encrypt}(PP, ID^*, t^*, M_1)\) to \(A\);

• Phase 2. A begins another query phase as Phase 1;

• Guess. A outputs a bit \(\beta'\) as a guess of \(\beta\);

The restrictions explicitly made on \(A\)'s queries in the game are as follows:

1) \(O_{KU}(t)\) and \(O_{CT}(ID, t)\) can only be queried in a sequential order in time. That is, the time \(t\) should be greater than or equal to the time of all previous queries;
2) \(O_{CT}(ID, t)\) cannot be queried if \(O_{KU}(t)\) was queried;
3) If \(O_{SK}(ID^*)\) was queried then \(O_{CT}(ID^*, t^*)\) must be queried, where \(t^* \leq t\);
4) \(O_{DK}(ID, t)\) cannot be queried before \(O_{KU}(t)\) was queried;
5) \(O_{DK}(ID^*, t^*)\) cannot be queried.

The adversary \(A\)'s advantage in the above game is defined as:

\[
\text{Adv}_{\text{RS-IBE,}A}^{\text{ND-RID-CPA}}(\lambda, T, N) = \left| \Pr[\beta' = \beta] - \frac{1}{2} \right|
\]

**Remark 1.** In the security game above, we do not prove a query oracle for the ciphertext update algorithm \(\text{CTUpdate}\) since the adversary can run it to a ciphertext just by using the public parameter \(PP\).

### 4 RS-IBE Resistant to Decryption Key Exposure

In this section, we first present a concrete construction of RS-IBE resistant to decryption key exposure, and then discuss its security and performance.

#### 4.1 Construction

Our construction involves two binary trees \(BT\) and \(T\) to manage identity and time period, respectively. More precisely, for identity revocation, we follow Boldyreva et al.'s [20] strategy. That is, given an identity \(ID\), we randomly store it in a leaf node \(\eta\) of \(BT\), and generate the corresponding secret key \(SK_{ID} = \{ (\theta, SK_{ID, \theta}) \}_{\theta \in \text{Path}(\eta)}\) as in previous RIBE schemes [20], [24]. If the user \(ID\) is not revoked at time period \(t\), there exists a node \(\theta \in \text{Path}(\eta) \cap \text{KUNodes}(BT, RL, t)\). Consequently, given the update key \(KU_t = \{ (\theta, KU_t, \theta) \}_{\theta \in \text{KUNodes}(BT, RL, t)}\) the user \(ID\) can obtain the decryption key for time period \(t\) by re-randomizing and combining \(\{(\theta, SK_{ID, \theta})\}\) and \(\{(\theta, KU_t, \theta)\}\).

However, for a user that is revoked at time period \(t\), there is no such node. As a result, the user cannot decrypt the ciphertext that is produced under its identity after the time period \(t\) (including \(t\)).

Let \(T = 2^\ell\) be the total number of system time periods. For each \(1 \leq i \leq T\), the time period \(t_i \in \{0, 1\}^\ell\) is associated with the \(i\)-th leaf node \(v_{t_i}\) of \(T\). Here, we arrange all leaf nodes of \(T\) in numerical order from left to right. Given a node \(v\) of \(T\), let \(b_{v, t_i} \in \{0, 1\}^\ell\) be the binary sequence corresponding to the path from the root node of \(T\) to \(v\), where \(0\) and \(1\) indicate that the path passes through the left and right child of the parent node, respectively. Conversely, given a string \(b \in \{0, 1\}^\ell\), let \(v_b\) be the node that has a path from the root node to it. Furthermore, denote by \(b_{v, t_i}\) and \(t_i\) the \(j\)-th bit of \(b_{v}\) and \(t_i\), respectively, and \(|b_{v}|\) the length of \(b_{v}\).

In addition, for each leaf node \(v\) of the binary \(T\), we define the following set: \(\mathcal{T}_v = \{ v \mid \text{Parent}(v) \in \text{Path}(v), v \notin \text{Path}(v_i) \cup \{ v_i \} \},\) where \text{Parent}(v) denotes the parent node of \(v\). As presented in [34], such a set features the following property:

![Fig. 3. An example of \(T\) with depth 3](image-url)
random vectors $u = (u_1, u_2, ..., u_n)$ in $G_1^{n+1}$ and $h = (h_0, h_1, ..., h_t)$ in $G_1^{t+1}$, and for each $ID \in \mathcal{I} = \{0, 1\}^n$ and $t \in \{0, 1\}^t$, define the following two functions $^3$:

$$F_u(ID) = u_0 \prod_{i=1}^n t \choose ID[i], \quad F_h(t) = h_0 \prod_{j=1}^t h_j[1].$$

Here, $ID[i]$ is the $i$th bit of $ID$.

3) Let the master secret key be $MSK = g_\theta^\ell$, and initialize the state $st$ with a binary tree $BT$ of depth $\log(N)$ and the revocation list $RL = \emptyset$.

4) Publish the public parameter as $PP = (G_1, G_2, e, g, g_1, g_2, u, h)$.

- **PKGen**($PP, MSK, ID$): For an identity $ID \in \mathcal{I}$, this algorithm generates its secret key according to the following way:
  1) Randomly choose and assign a leaf node $\eta$ of $BT$ to $ID$.
  2) For each node $\theta \in Path(\eta)$,
     a. Recall $g_{\theta,0}$ from $BT$ if it has been defined previously.
     Otherwise, pick $g_{\theta,0} \leftarrow R G_1$ and store the pair $(g_{\theta,0}, g_{\theta,1} = g_2/g_{\theta,0})$ in the node $\theta$.
     b. Choose $r_{\theta,0} \leftarrow R Z_p^*$ and compute:

$$SK_{ID,\theta} = (SK_{\theta,0}, SK_{\theta,1}) = (g_{\theta,0}^\ell F_u(ID)^{r_{\theta,0}}, g_{\theta,0}^{r_{\theta,0}}).$$

3) Update the state as $st = BT$, and then return the secret key $SK_{ID,t} = \{\{\theta, SK_{\theta,0}ID,0\}\} \theta \in Path(\eta)$.

- **KeyUpdate**($PP, MSK, RL, t, sk$): For each node $\theta \in KUNodes(BT, RL, t)$, do the following:
  1) Extract the pre-defined value $g_{\theta,1}$ from $BT$.
  2) Choose $r_{\theta,1} \leftarrow R Z_p^*$ and set

$$TU_{t,\theta} = (TKU_{\theta,0}, TKU_{\theta,1}) = (g_{\theta,1} \cdot F_h(t)^{r_{\theta,1}}, g_{\theta,1}^{r_{\theta,1}}).$$

3) Return $TKU = \{\{\theta, TKU_{\theta,0}, TKU_{\theta,1}\} \theta \in KUNodes(BT, RL, t)$.

- **DKGen**($PP, SK_{ID,1}$): If $ID$ was revoked during time period $t$, return $\bot$. Otherwise, there exists some node $\theta \in Path(\eta) \cap KUNodes(BT, RL, t)$, for this node $\theta$, parse $SK_{ID,\theta} = (SK_{\theta,0}, SK_{\theta,1})$ and $TU_{t,\theta} = (TKU_{\theta,0}, TKU_{\theta,1})$. Then, choose $r_0, r_1 \leftarrow R Z_p^*$, compute and return

$$DK_{ID,t} = (DK_{t,1}, DK_{t,2}, DK_{t,3}) = (SK_{\theta,0} \cdot TKU_{\theta,0} \cdot F_u(ID)^{r_{\theta,0}} \cdot F_h(t)^{r_{\theta,1}}, SK_{\theta,1} \cdot g_{\theta,1} \cdot TKU_{\theta,1} \cdot g_{\theta,1}^{r_{\theta,1}}).$$

- **Encrypt**($PP, ID, t, M$): To encrypt $M \in G_2$ with $ID$ at time period $t$, choose $s_t \leftarrow R Z_p^*$, select $s_t \leftarrow R Z_p^*$ for each node $\theta \in T_t$. Particularly, let $s_{\eta,1} = s_t$. Then, set the ciphertext as $CT_{ID,t} = \{ID, t, C_0, C_1, C_2, \{C_v\}_{v \in \mathcal{T}_t}\}$, where $C_0 = M \cdot e(g_1, g_2)^{s_t}, C_1 = g_{\theta,1}^{s_t}, C_2 = F_h(ID)^{s_t}, C_v = \{C_v,0, C_v,1, C_v,2, C_v,3, ..., C_v,t\}$,

$$ = \Big(h_0 \prod_{j=1}^t h_j[1]^{s_t}, h_{\theta,1}[1, h_{\theta,1}[1, h_{\theta,1}[2, ..., h_{\theta,1}[t].$$

4. As indicated in [29], a pseudo-random function can be used to re-compute $g_{\theta,0}$ when necessary instead of having to store it in the node $\theta$.

- **CTUpdate**($PP, CT_{ID,t}, t'$): Parse the ciphertext as $CT_{ID,t'} = \{ID, t', C_0, C_1, C_2, \{C_v\}_{v \in \mathcal{T}_t}\}$, where $C_0 = C_v,0, C_v,1, C_v,2, ..., C_v,t$. To update the ciphertext from time period $t$ to $t' \geq t$, do the following:
  1) For each node $v' \in \mathcal{T}_t$, find a node $v \in \mathcal{T}_t$ such that $b_v$ is a prefix of $b_{v'}$.
  2) Choose $s_{v'} \leftarrow R Z_p^*$ such that $s_{v'} \leftarrow R Z_p^*$ for each node $v' \in \mathcal{T}_t$. Particularly, let $s_{v,1} = s_{v'}$.
  3) Compute

$$C_0' = C_0 \cdot e(g_1, g_2)^{s_{v'}} \cdot C_1' = C_1 \cdot g_{\theta,1}^{s_{v'}}, C_2' = C_2 \cdot F_h(ID)^{s_{v'}}, C_v' = \{C_v,0', C_v,1', C_v,2', ..., C_v,t\},$$

$$ = \Big(C_v,0 \cdot h_0 \prod_{j=1}^t h_j[1]^{s_{v'}} + C_v,1 \cdot h_{\theta,1}[1, C_v,2 \cdot h_{\theta,1}[1, ..., C_v,t \cdot h_{\theta,1}[t].$$

4) Return $CT_{ID,t'} = \{ID, t', C_0', C_1', C_2', \{C_v'\}_{v \in \mathcal{T}_t}\}$.

- **Decrypt**($PP, CT_{ID,t}, DK_{ID,t}$): If $t' < t$ return $\bot$. Otherwise, update the ciphertext $CT_{ID,t'}$ to get $CT_{ID,t''}$, and parse $CT_{ID,t'} = \{ID, t', C_0', C_1', C_2', C_v', \{C_v\}_{v \in \mathcal{T}_t}\}$ and $DK_{ID,t'} = \{DK_{t,1}, DK_{t,2}, DK_{t,3}\}$. Then, return

$$M = C_0 \cdot e(C_1, DK_{t,1}) \cdot e(C_2, DK_{t,2}) \cdot e(C_v', \{C_v\}_{v \in \mathcal{T}_t}).$$

- **Revoke**($PP, ID, RL, t, st$): To revoke $ID$ at time period $t$, update the revocation list by $RL = RL \cup \{(ID, t')\}$ and return the updated $RL$.

**Correctness.** We verify the correctness of our scheme as follows: Firstly, given a node $\theta \in KUNodes(BT, RL, t) \cap Path(\eta)$, we have that

$$DK_{\theta,t} = (SK_{\theta,0} \cdot TKU_{\theta,0} \cdot F_u(ID)^{r_{\theta,0}} \cdot F_h(t)^{r_{\theta,1}}, SK_{\theta,1} \cdot g_{\theta,1} \cdot TKU_{\theta,1} \cdot g_{\theta,1}^{r_{\theta,1}}).$$

Then, for a ciphertext $CT_{ID,t} = \{ID, t, C_0, C_1, C_2, \{C_v\}_{v \in \mathcal{T}_t}\}$, we note that $C_v,0 = F_h(t)^{s_v}$. Thus, it holds that

$$M \cdot e(g_1, g_2)^{s_v} \cdot e(g_{\theta,1}^{s_v}, g_{\theta,1}^{s_v} \cdot F_u(ID)^{r_{\theta,0} + r_{\theta,1}} \cdot F_h(t)^{r_{\theta,1} + 1}) \cdot e(F_u(ID)^{r_{\theta,1}}, g_{\theta,1}^{s_v} \cdot e(F_h(t)^{s_v}, g_{\theta,1}^{s_v} + 1)) = M \cdot e(g_1, g_2)^{s_v} \cdot e(g_{\theta,1}^{s_v}, g_{\theta,1}^{s_v} + 1)) = M.$$
where \( q \) is the maximum number\(^5 \) of secret key queries and decryption key queries, and \( T = 2^l \) is the total number of time periods.

**Proof.** Given a PPT adversary \( A \) breaking the IND-RID-CPA security of the proposed RS-IBE scheme, we will construct an algorithm \( C \) to solve the decisional \( l \)-BDHE problem. More precisely, given a random instance of the \( l \)-BDHE problem in the form of a tuple \((G_1, G_2, c, p, f, D)\) where \( f = (g, g^\ell, f_1, ... f_{2l}, ... f_x) \) and \( f_i = g^{a_i} \) in \( G_1 \) for \( 1 \leq i \leq 2l \), the algorithm \( C \) can decide if \( D = c(f_{l+1}, g^\ell) \) by simulating the experiment according to the following steps.

**Setup.** The algorithm \( C \) randomly guesses a time period the adversary \( A \) will choose to be challenged. Denote it by \( t^* \). To generate public parameter \( PP \), the algorithm \( C \) proceeds as follows:

1. Choose \( a' \leftarrow \mathcal{R} \mathbb{Z}_p \) and let \( g_1 = f_1 g^{a'} \) and \( g_2 = f_\ell \), which implicitly sets as \( \alpha = (a + a') \) and the master secret as \( MSK = g_2^{a'} \), an unknown value to \( C \).
2. Let \( m = 4q \) and select an integer \( \rho \leftarrow \mathcal{R} \{0, 1, ..., n\} \). Furthermore, choose \( n + 1 \) integer random integers \( x_0, x_1, ... , x_n \in \{0, 1, ... , m - 1\} \) and another \( n + 1 \) random integers \( y_0, y_1, ..., y_n \in \mathbb{Z}_p \). For an identity \( ID \in \{0, 1\}^n \), define the following:

\[
J(ID) = (p - m\rho) + x_0 + \sum_{i=1}^{n} ID[i]x_i,
\]

\[
K(ID) = y_0 + \sum_{i=1}^{n} ID[i]y_i.
\]
3. Assign \( u_0 = g_2^{x_0 - m\rho} g^{u_0} \) and \( u_i = g_2^x g^{u_i} \) for each \( 1 \leq i \leq n \), and let \( u = (u_0, u_1, ..., u_n) \). Note that the above assignment implies that \( F_u(ID) = g_2^{J(ID)} g^K(ID) \).
4. Choose random integers \( \gamma_0, \gamma_1, ..., \gamma_e \in \mathbb{Z}_p \) and set \( h_0 = g^{\gamma_0} \prod_{i=1}^l f_i^{u(i)} \) and \( h_j = g^{\gamma_j} f_{l+j}^{-1} \) for \( 1 \leq j \leq \ell \). Let \( h = (h_0, h_1, ..., h_\ell) \).
5. Publish the public parameter as

\[ PP = (G_1, G_2, c, e, g, g_1, g_2, u, h) \]

Before starting to answer the adversary \( A \)'s queries, the algorithm \( C \) flips a coin \( c_{type} \leftarrow \mathcal{R} \{0, 1\} \) to guess that \( A \) belongs to which type of adversaries, which are distinguished as follows:

- **Type-1 adversaries** (i.e., \( c_{type} = 0 \)) choose to query \( O_{SK}(ID^*) \) at some point, but \( ID^* \) is revoked before the challenged time period \( t^* \).
- **Type-2 adversaries** (i.e., \( c_{type} = 1 \)) do not query \( O_{SK}(ID^*) \) at any time.

Depending on \( A \)'s type (i.e., the bit \( c_{type} \)), the algorithm \( C \) deals with \( A \)'s behaviors by using different strategies separately.

- **The case** \( c_{type} = 0 \).

Denote by \( ID_k \), the input of \( C \)'s \( k \)th query on \( O_{SK}(\cdot) \). The algorithm \( C \) initially chooses \( k^* \leftarrow \mathcal{R} \{1, ..., q\} \) as a guess that \( A \)'s \( k^* \)th key query happens to be \( O_{SK}(ID^*) \) (i.e., \( ID_{k^*} = ID^* \)) with probability \( 1/q \), and randomly selects a leaf node \( \eta^* \) of \( BT \) to store \( ID^* \).

**Phase 1.** \( C \) responds to \( A \)'s queries according to the following way:

- \( O_{KU}(t) \): For each node \( \theta \in \text{KUNodes}(BT, RL, t) \), the algorithm \( C \) does the following:
  1. Retrieve \( Y_\theta \) from \( \theta \) if it was defined. Otherwise, it chooses \( Y_\theta \leftarrow \mathcal{R} G_1 \) and stores it in \( \theta \).
  2. If \( t = t^* \), it must be that \( \theta \notin \text{Path}(\eta^*) \), since \( ID^* \) is revoked before the time period \( t^* \). The algorithm \( C \) chooses \( r_{\theta,1} \leftarrow \mathcal{R} \mathbb{Z}_p \), and computes

\[
KU_{t,\theta} = (KU_{\theta,0}, KU_{\theta,1}) = (Y_\theta^{-1} F_h(t)^{e\omega}, g^{r_{\theta,1}}).
\]

Observe that \( KU_{t,\theta} \) is correctly formed as its assignment implicitly sets \( g_{\theta,1}^{\alpha} = Y_\theta^{-1} \).

3. If \( t \neq t^* \), there exists an integer \( 1 \leq l \leq \ell \) such that \( t^*[l] \neq [l] \). Without loss of generality, assume \( l \) is the smallest such integer. If \( \theta \notin \text{Path}(\eta^*) \), the algorithm \( C \) does the same as in the case \( t = t^* \) otherwise. \( C \) performs as follows: Choose \( r_{\theta,1} \leftarrow \mathcal{R} \mathbb{Z}_p \) and let \( r_{\theta,1} = \frac{g_1^{d_{\ell} - [l] - [l]}}{[l]} + r_{\theta,1}^\prime \), and set

\[
KU_{t,\theta} = (KU_{\theta,0}, KU_{\theta,1}) = (Y_\theta^{-1} g_2^\ell F_h(t)^{e\omega}, g^{r_{\theta,1}}).
\]

Observe that \( KU_{t,\theta} \) is well-defined in this case as its assignment implicitly sets \( g_{\theta,1}^{\alpha} = Y_\theta^{-1} g_2^\ell \).

4. Return \( KU_t = \{ \theta, KU_{t,\theta} \}_{\theta \in \text{KUNodes}(BT, RL, t)} \).

- **O_{SK}(ID_k):** Let \( ID_k \) be the input of the \( k \)-th private key query.

  - For \( k \neq k^* \), if \( ID_{k} = (\cdot) \neq 0 \), the algorithm \( C \) aborts. Otherwise, \( C \) randomly chooses a node \( \eta \) from \( BT \) and stores \( ID_k \) in \( \eta \), and then for each \( \theta \in \text{Path}(\eta) \) does the following:
    1. Recall \( Y_\theta \) if it was defined. Otherwise, choose \( Y_\theta \leftarrow \mathcal{R} G_1 \).
    2. If \( \theta \in \text{Path}(\eta^*) \), choose \( r_{\theta,0} \leftarrow \mathcal{R} \mathbb{Z}_p \) and compute

\[
SK_{1D_k,\theta} = (SK_{\theta,0}, SK_{\theta,1}) = (Y_\theta \cdot F_h(ID_k)^{e\omega}, g^{r_{\theta,0}}).
\]

Observe that \( KU_{t,\theta} \) is well-defined in this case as its assignment implicitly sets \( g_{\theta,1}^{\alpha} = Y_\theta g_2^\ell \).

3. If \( \theta \notin \text{Path}(\eta^*) \), choose \( r_{\theta,0} \leftarrow \mathcal{R} \mathbb{Z}_p \) and set \( r_{\theta,0} \leftarrow \frac{g_1^{d_{\ell} - [l]}}{[l]} + r_{\theta,0}^\prime \), and let

\[
SK_{1D_k,\theta} = (SK_{\theta,0}, SK_{\theta,1}) = (Y_\theta \cdot g_2^\ell \cdot F_h(ID_k)^{e\omega}, g^{r_{\theta,0}}).
\]

Observe that \( KU_{t,\theta} \) is well-defined in this case as its assignment implicitly sets \( g_{\theta,1}^{\alpha} = Y_\theta g_2^\ell \). In addition, we can see that \( SK_{1D_k,\theta} \) is also computable for \( C \):

\[
SK_{0,\theta} = Y_\theta \cdot g_2^{a' \omega} \cdot (g_2^{J(ID_k)} g^K(ID_k))^{e\omega} = Y_\theta \cdot g_2^{\omega} \cdot (g_2^{J(ID_k)} g^K(ID_k))^{e\omega}.
\]
and $SK_{\theta,1} = g^{\gamma_0 \cdot \ell} = g^{\gamma_0 \cdot \ell} \cdot f_1^{\frac{1}{\gamma_0 \cdot \ell}}$.

- For $k = k^*$ (i.e., $ID_k = ID^*$), if $J(ID_k) \neq 0$, the algorithm $C$ aborts. Otherwise, for each $\theta \in \text{Path}(\eta^*)$, the algorithm $C$ proceeds as follows:

1) Retrieve $Y_0$ from $BT$ if it was defined. Otherwise, choose $Y_0 \in \mathbb{Z}_p$.

2) Select $r_{\theta,0} \in \mathbb{Z}_p$ and compute $SK_{IS^*,\theta} = (SK_{\theta,0}, SK_{\theta,1})$,

$$= (Y_0 \cdot F_{\omega}(ID^*)^{\gamma_0 \cdot \ell}, g^{\gamma_0 \cdot \ell}).$$

Observe that $KU_1,\theta$ is well-defined in this case as its assignment sets $g_{0,0}^\theta = Y_0$.

- $O_{DK}(ID, t)$: The algorithm $C$ conducts a query $O_{SK}(ID)$, and then runs $DKGen(PP, SK_{ID}, KU_1)$. Now we show that by the definitions of $O_{KU}(\cdot)$ and $O_{SK}(\cdot)$, the output of $O_{DK}(\cdot)$ is also correctly formed. Given the input $(ID, t)$, we distinguish them into the following three sub-cases:

- In case $ID = ID^*$, it must be that $t \neq t^*$.

By the definitions, for each $\theta \in \text{Path}(\eta^*) \cap \text{KUNodes}(PP, RL, t)$, we have that

$$KU_{1,\theta} = (Y_0 \cdot g_{0,0}^\theta \cdot F_h(t)^{\gamma_0 \cdot \ell}, g^{\gamma_0 \cdot \ell})$$

$$= (Y_0 \cdot g_{0,0}^\theta \cdot F_h(t)^{\gamma_0 \cdot \ell}, g^{\gamma_0 \cdot \ell}).$$

This implies that $g_{0,0}^\theta \cdot g_{0,1}^\theta = g_{0,0}^\theta$. Thus, the decryption key $DK_{ID, t^*}$ is also correctly formed.

- In the case $ID \neq ID^*$ and $t \neq t^*$, for each node $\theta \in \text{KUNodes}(PP, RL, t) \cap \text{Path}(\eta^*)$, if $\theta \in \text{Path}(\eta^*)$ then the case is the same as the case $ID = ID^*$. Otherwise, the case is the same as the case $ID \neq ID^*$ and $t = t^*$.

**Challenge.** Given $(M_0, M_1)$ and $(ID^*, t^*)$ on which the adversary $A$ wishes to be challenged, if either $ID^* \neq ID_k$ or $t^* \neq t^*$, the algorithm $C$ aborts. Otherwise, it randomly flips a coin $\beta \in \{0, 1\}$, and generates the challenged ciphertext as follows:

1) Compute $C_0^* = M_0 \cdot e(g^\alpha, f_{t+1})^{\alpha^*}, C_1^* = (g^\gamma)^{-1}, C_2^* = (g^\gamma)^{K(Id^*)};$

2) For the node $v_{t^*}$, compute $C_{v_{t^*}}^* = (C_{v_{t^*}}^*, g) = ((g^\gamma)^{\gamma_0 \cdot \sum\ell \in \tau^*: \gamma_j})$;

3) For each node $v \in \mathcal{T}_{t^*} \setminus \{v_{t^*}\}$, choose $s_v \in \mathbb{Z}_p$ and compute $C_v^* = (C_v^*; C_v^{[b_v]}; C_v^{[b_v]+1}; C_v^{[b_v+1]}; C_v^{[b_v+1]+1}; \ldots)$

$$= (\prod_{j=1}^{b_v} h_{j}^{v_i} s_{v}^{v_i}; h_{1}^{v_i} b_{v_i}^{v_i}; h_{b_{v_i}+1}^{v_i}; h_{b_{v_i}+1+1}^{v_i}; \ldots);$$

4) Return the challenged ciphertext

$$CT_{ID^*, t^*} = (C_0^*, C_1^*, C_2^*; \{C_v^*\}_{v \in \mathcal{T}_{t^*}}).$$

Now, we show that if $D = e(g^\alpha, f_{t+1})$ then $CT_{ID^*, t^*}$ is correctly formed. To this end, recall that $F_h(ID^*) = g^{K(ID^*)}$ and $F_h(t^*) = g^{\gamma_0 \cdot \sum\ell \in \tau^*: \gamma_j}$, as well as observe that

$$D \cdot e(g^\alpha, f_{t+1})^{\alpha^*} = e(g^\alpha, f_{t+1}) \cdot e(g^{\gamma_0 \cdot \ell}, f_{t+1})$$

$$= e(g^\alpha, f_{t+1}) \cdot e(g^{\gamma_0 \cdot \ell}, f_{t+1})$$

$$= e(g^\alpha \cdot \gamma_0, f_{t+1}) = (g_1, g_2)^{\gamma_0}.$$
In addition, if $D$ is a random element in $G_2$, then $M_3$ is perfectly hidden from the adversary $A$'s view.

**Phase 2.** $C$ proceeds the same as in Phase 1.

**Guess.** Eventually, the adversary $A$ outputs a bit $\beta'$ as a guess of $\beta$. If $\beta = \beta'$, the algorithm $C$ outputs 0, and 1 otherwise.

- The case $c_{\text{type}} = 1$.

Recall that the adversary $A$ does not query $O_{SK}(ID^*)$ in this case at any time. However, $A$ may make several decryption key queries on the challenged identity $ID^*$. Denote the time of such queries by $\text{Count}^*$. The algorithm $C$ flips an unbiased coin to guess if $\text{Count}^* = 0$ or not. If not, $C$ randomly guesses that $A$’s $k^*$th decryption key query happens to be the first one on $ID^*$.

- The case $\text{Count}^* = 0$.

**Phase 1.** The algorithm $C$ answers $A$’s queries as follows:

- $O_{KU}(t)$: For each node $\theta \in \text{KUNodes}(BT, RL, t)$, the algorithm $C$ does the following:
  1. Recall $Y_\theta$ from $BT$ if it was defined. Otherwise, choose $Y_\theta \leftarrow R G_1$ and store it in the node $\theta$.
  2. Select $r_{\theta, 0} \leftarrow R Z_p$, and compute $KU_{\theta, \theta} = (KU_{\theta, 0} . KU_{\theta, 1}) = (Y_\theta^{-1} \cdot F_h(k(t))^{\gamma^0} \cdot \gamma^{\nu^1})^\theta$.
  3. Return $KU_t = \{(\theta, KU_{\theta, \theta})\}_{\theta \in \text{KUNodes}(BT, RL, t)}$.

- $O_{SK}(ID_k)$: If $J(ID_k) \neq 0$, the algorithm $C$ aborts. Otherwise, to generate the secret key for the identity $ID_k$, the algorithm $C$ proceeds as follows:
  1. Randomly choose a leaf node $\eta$ from $BT$ and store $ID$ in $\eta$.
  2. For each node $\theta \in \text{Path}(\eta)$, retrieve $Y_\theta$ from $BT$ if it was defined. Otherwise, choose $Y_\theta \leftarrow R G_1$ and store it in the node $\theta$.
  3. Choose $r_{\theta, 0} \leftarrow R Z_p$ and let $r_{\theta, 0} = r_{\theta, 0} \cdot r_{\theta, 0}$ for each node $\theta \in \text{Path}(\eta)$, and set $SK_{ID_k, \theta} = (SK_{\theta, 0} . SK_{\theta, 1})$.

\[
SK_{ID_k, \theta} = (SK_{\theta, 0} . SK_{\theta, 1}) = (Y_\theta \cdot g_2^\alpha \cdot F_u(ID_k)^{\gamma^0} \cdot \gamma^{\nu^1}).
\]

As shown in the case $c_{\text{type}} = 0$, the value $SK_{ID_k, \theta}$ is correctly formed, and is computable for the algorithm $C$.

4. Return $SK_{ID_k} = \{(\theta, SK_{ID_k, \theta})\}_{\theta \in \text{Path}(\eta)}$.

- $O_{DK}(ID, t)$: The algorithm $C$ queries $O_{SK}(ID)$ and subsequently runs $\text{DKGen}(PP, SK_{ID}, KU_t)$, and returns the corresponding output. Similar to the case $c_{\text{type}} = 0$, we can verify that the output of the decryption key query is well defined.

**Challenge.** Given $(M_0, M_1)$ and $(ID^*, t^*)$, the algorithm $C$ checks if $J(ID^*) = 0$ and $t^* = t^*$. If not, $C$ aborts. Otherwise, $C$ generates the challenged ciphertext according to the same way as in the case $c_{\text{type}} = 0$.

- The case $c_{\text{type}} = 0$.

**Phase 2.** $C$ proceeds the same as in Phase 1.

**Guess.** $C$ performs the same as in the case $c_{\text{type}} = 0$.

**Analysis of $C$.** To enable the algorithm $C$ to complete the experiment without aborting, the following conditions are required to be fulfilled:

1. $E_1: t^* = t^*$;
2. In the case $c_{\text{type}} = 0$:
   - $E_{2,1}$: For $O_{SK}(ID_k^*)$, it must be $ID_k^* = ID^*$;
   - $E_{2,2}$: For $1 \leq k \neq k^* \leq q$, it must be $J(ID_k) \neq 0$;
   - $E_{2,3}$: $J(ID^*) = 0$.
3. In the case $(c_{\text{type}} = 1 \land \text{Count*} = 0)$:
   - $E_{3,1}$: For $1 \leq k \leq q$, it must be $J(ID_k) = 0$;
   - $E_{3,2}$: $J(ID^*) = 0$;
4. In the case $(c_{\text{type}} = 1 \land \text{Count*} \neq 0)$:
   - $E_{4,1}$: For $1 \leq k \leq q$, it must be $J(ID_k) = 0$;
   - $E_{4,2}$: For $O_{DK}(ID_k, t)$, it must be $ID_k = ID^*$;
   - $E_{4,3}$: $J(ID^*) = 0$.

Denote by $E$ the event that $C$ does not abort the experiment, we can see that
\[
E = (E_1 \land E_{2,1} \land E_{2,2} \land E_{2,3}) \lor (E_1 \land E_{3,1} \land E_{3,2}) \lor (E_1 \land E_{3,1} \land E_{3,2} \land E_{3,3}).
\]

Furthermore, by using Waters’s [38] “artificial abort” technique, we obtain that
\[
\begin{align*}
\Pr[E_1 \land (E_{2,1} \land E_{2,2} \land E_{2,3})] & \geq \frac{1}{2} \cdot \frac{1}{T} \cdot \frac{1}{q} \cdot \frac{1}{8q(n+1)} \\
\Pr[E_1 \land (E_{3,1} \land E_{3,2})] & \geq \frac{1}{4} \cdot \frac{1}{T} \cdot \frac{1}{8q(n+1)} \\
\Pr[E_1 \land (E_{3,1} \land E_{3,2} \land E_{3,3})] & \geq \frac{1}{4} \cdot \frac{1}{T} \cdot \frac{1}{q} \cdot \frac{1}{8q(n+1)}
\end{align*}
\]
experiment, and thus abort, if Mcrypted message

However, if D is a random element from G₂ then encrypted message \( M_D = g^{ρ_D} \) is perfectly hidden from the \( A \)'s view, and thus

Pr[\( C(f, D = e(g^s, g^{g^{ρ_D}+1}) \) then C perfectly simulates the experiment, and thus

By combining the above equalities, we get that

\[
\text{Adv}_{\text{C}}^{\text{DBDH}^f}(\lambda) = \left| \Pr[C(f, D = e(g^s, g^{g^{ρ_D}+1})) = 0] - \Pr[C(f, D \leftarrow G_2) = 0] \right| \\
\geq \frac{1}{32Tq^2(n + 1)} \cdot \text{Adv}_{\text{RS-IBE}, A}^{\text{IND-RID-CPA}}(\lambda, T, N).
\]

This completes the proof.

### 4.3 Performance discussions

In this section, we discuss the performance of the proposed RS-IBE scheme by comparing it with previous works in terms of communication and storage cost, time complexity and functionalities, which are summarized in Table 1, Table 2 and Table 3.

From Table 1 we can see that the sizes of private key and update key in schemes [22], [24] and our scheme are all upper bounded by \( O(r \log N/r) \), since these schemes all utilize binary data structure to achieve revocation. On the other hand, Liang et al.'s [26] scheme involves a broadcast encryption scheme to distribute update key such that their scheme has constant sizes of private key and update key. Furthermore, by delegating the generation of re-encryption key to the key authority, the ciphertext size of their scheme also achieves constant. However, to this end, the key authority has to maintain a data table for each user to store the user's secret key for all time periods, which brings \( O(T) τ_{G_1} \).
storage cost for the key authority. Conversely, the ciphertext size of our scheme is just linear in $\log(T)^2$. In addition, we note that in all listed schemes, the private key generator needs to periodically produce an update key; it must be online if each time period is rather short, e.g., an hour. However, from the perspective of practical applications, the frequency of updating users’ decryption keys should not be too small. A time period like a week, half a month or a moth is more desirable. As a consequence, the private key generator just needs to produce an update key for the next period when the current time period is over. Thus the PKG does not need to be always online. Another limitation of these listed schemes is that the generated ciphertext has the size linear with the number of receivers. To overcome this issue, a natural manner is to construct a similar scheme in the setting of broadcast encryption.

On the aspect of time complexity, as illustrated in Table 2, the enumerated schemes all have constant time of
decryption\(^6\). For two schemes supporting ciphertext update, the time complexity of ciphertext update in Liang et al.’s scheme is linear in \(N\) since the key authority needs to produce a re-encryption key for each user to re-encrypt the ciphertext. However, the time complexity of ciphertext update in our scheme is linear in \(\log(T)^2\).

As shown in Table 3, the four schemes are all proved secure in an adaptive-secure model, and can also provide backward secrecy since they all supports identity revocation. But the security of our scheme is built upon a relatively strong security assumption, decisional \(\ell\)-DBHE assumption. The schemes [22], [24] and ours update user’s secret keys in a public way, namely, the update key is available for all users. However, Liang et al.’s [26] scheme involves the method of broad encryption to update user’s secret key such that only non-revoked users can obtain the update key. Consequently, their scheme cannot resist collusion attack of revoked users and non-revoked users. Compared with the schemes [22] and [24], Liang et al.’s [26] scheme and ours can both provide forward secrecy by additionally introducing the functionality of ciphertext update. But the procedure of ciphertext update in Liang et al.’s [26] scheme is performed in a private and interactive way, since it requires the key authority to periodically produce and provide re-encryption keys for the cloud server to update ciphertext. However, in our schemes, the cloud server itself can update ciphertext by just using public parameter.

### 4.4 Implementation

To show the practical applicability of the proposed RS-IBE scheme, we further implement it using codes from the Pairing-Based Cryptography library version 0.5.14 [39]. Specifically, we use the symmetric supersingular curve \(y^2 = x^3 + x\), where the base field size is 512-bit and the embedding degree is 2. The implementation is taken on a Linux-like system (Win7 + MinGW) with an Intel(R) Core(TM) i5 CPU (650@3.20GHz) and 4.00 GB RAM.

In the implementation, we set the number of users to be \(N = 8\) and the revoked uses to be \(R = 4\) (the nodes \(\eta_2, \eta_3, \eta_4, \eta_7\) in Figure 2 are revoked). In Figure 5, Figure 6 and Figure 7, we present the running time of the basic algorithms, i.e., PKGen, KeyUpdate, DKGen, Encrypt, CTUpdate and Decrypt, for different choice of the total number of time periods \(T \in \{2^3, 2^6, 2^9, 2^{12}, 2^{14}, 2^{16}, 2^{18}\}\). To generate the experimental results, we perform as the following procedure: generate the private key and encrypt a message at the initial time period, then, periodically update the private key and the ciphertext, and decrypt the ciphertext. For a small number of time periods: \(T \in \{2^3, 2^6, 2^9\}\), the running time of each algorithm is obtained by computing the average of running the above procedure 100 times. While, for a large number of time periods: \(T \in \{2^{10}, 2^{12}, 2^{14}, 2^{16}, 2^{18}\}\), the running time for each algorithm is obtained by running the above procedure only once, and the running time for update algorithm is the mean of the first 512 time periods. We observe that, the time costs of the algorithms PKGen, KeyUpdate, DKGen and Decrypt are independent of the total number of time periods, and no more than 40 milliseconds. On the other hand, it takes less than 1 second for the user to initially encrypting the message, which would be shared on the cloud. Although the time cost of the algorithm CTUpdate is apparently greater than other algorithms, it is run by a cloud server with powerful capability of computation. Thus, our RS-IBE scheme is feasible for practical applications.

### 5 Conclusions

Cloud computing brings great convenience for people. Particularly, it perfectly matches the increased need of sharing data over the Internet. In this paper, to build a cost-effective and secure data sharing system in cloud computing, we proposed a notion called RS-IBE, which supports identity revocation and ciphertext update simultaneously such that a revoked user is prevented from accessing previously shared data, as well as subsequently shared data. Furthermore, a concrete construction of RS-IBE is presented. The proposed RS-IBE scheme is proved adaptive-secure in the standard model, under the decisional \(\ell\)-DBHE assumption. The comparison results demonstrate that our scheme has advantages in terms of efficiency and functionality, and thus is more feasible for practical applications.
